Abstract
The Lessepsian foraminiferan Amphistegina lobifera is particularly numerous on algae in shallow water. We sampled foraminifers from three algae (Cystoseira spp., Padina pavonica and Halopteris sp.) within the 0.75 - 2.0 m depth zone from five different sites around the island of Malta. There was a significant difference in the population density of live Amphistegina between the algae studied with Halopteris being preferred to Padina and with very sparse populations on Cystoseira.

Keywords: Alien species, Behaviour, Foraminifera, Malta Channel

Introduction
The symbiont bearing foraminiferan Amphistegina lobifera is a Lessepsian immigrant in the Mediterranean Sea where it now occurs in Tunisia, Egypt, Libya, Turkey, Greece, Malta, Italy, Israel and Lebanon [1]. This foram has been very successful in some areas (e.g. Turkey and Greece) where it can constitute 80-90% of total foraminiferal abundance [2], reducing the native foraminiferal diversity by up to 30% [3]. In shallow water, A. lobifera is particularly abundant on algae, but casual observations suggested preference for particular types. Field studies were carried out to test this hypothesis.

Methods
Five replicate samples of each of three different algae (Cystoseira spp., Padina pavonica and Halopteris sp.) were obtained from the 0.75 - 2.0 m depth zone from five sites in Malta (Anchor Bay, Bahar ic-Caghqaq, Fond Ghadir, Ghar Lapal, Marsaskala) (Fig. 1), using a 10 cm x 10 cm quadrat. Sampling was undertaken between August and November 2017. With one exception, the algae chosen were present at all sites (Padina was not found at Fond Ghadir) and were the dominant species in the sampled areas. In the laboratory, any Amphistegina lobifera present on the algal thalli were removed and stained in 0.25 g/L Rose Bengal in 70% ethanol for 48 hours. Individuals were then separated into three categories: living, uncertain and dead. The living forams stained pink whilst the dead ones retained their original colour; those with an in-between colour were classified as ‘uncertain’.

Results and Discussion
Living A. lobifera accounted for 80-93 % of the amphisteginids present on the algal thalli. The mean abundances of living specimens recorded from the different algae are presented in Table 1. There was a statistically significant difference in abundance of living A. lobifera between the different algae (Kruskal-Wallis H-test; p=0.004), with Halopteris being preferred to Padina at all sites, and Cystoseira hardly having any forams at all.

In shallow water, amphisteginids are prone to dislodgement by wave action, especially when they are still juvenile (<500 μm diameter) [4], while high light intensities can cause bleaching of their photosynthetic symbionts [5]. Both factors may contribute to the observed preference for Halopteris sp. since the thallus of this species consists of very dense lateral branches and axillary hairs, making it ideal for secure attachment and also serving to reduce light penetration. Padina pavonica was the next preferred species. Most forams on this alga were found on the underside of the thalli, suggesting that the broad thallus can act as a ‘shield’ from wave action while also having a shading effect. Cystoseira spp. was the least preferred algal species at the studied depths, most likely due to the larger spacing between the branches of the thallus. At greater depths the situation may be different due to decreased water movement and reduced need to shelter from sunlight.
